## The Linear Regression Model

Bas Machielsen

2025-06-13

### What is Econometrics?

#### **Econometrics** is the use of statistical methods to:

- 1. **Estimate** economic relationships.
- 2. **Test** economic theories.
- 3. Evaluate and implement government and business policy.
- 4. Forecast economic variables.

It's where economic theory meets real-world data. Theory proposes relationships (e.g., Law of Demand), but econometrics tells us the magnitude and statistical significance of these relationships.

## Why study econometrics?

- It allows you to quantify the relationships that you learn about in your other economics courses.
  - By how much does demand fall if we raise the price by 10%?
  - ▶ What is the effect of an additional year of education on future wages?
  - It helps distinguish between correlation and causation.
  - It is an essential tool for empirical research in economics and finance, and a highly valued skill in the job market.

#### The Nature of Economic Data

The type of data we have determines the econometric methods we should use.

- ► Cross-Sectional Data: A snapshot of many different individuals, households, firms, countries, etc., at a *single point in time*.
  - Example: A survey of 500 individuals in 2023, with data on their wage, education, gender, and age.
- ► **Time Series Data:** Observations on a single entity (e.g., a country, a company) collected over *multiple time periods*.
  - Example: Data on U.S. GDP, inflation, and unemployment from 1950 to 2023.

## The Nature of Economic Data (Cont.)

- ▶ Pooled Cross-Sections: A combination of two or more cross-sectional datasets from different time periods. The individuals are different in each period.
  - Example: A random survey of households in 1990, and another *different* random survey of households in 2020.
- ▶ Panel (or Longitudinal) Data: The same cross-sectional units are followed over time.
  - Example: Tracking the wage, education, and city of residence for the same 500 individuals every year from 2010 to 2020.

### The Concept of a Model

### The Population Regression Function (PRF)

Let's say we are interested in the relationship between wages (y) and years of education (x). Economic theory suggests a positive relationship.

We can model the *average* wage for a given level of education. This is the **Population Regression Function** (PRF):

$$E(y|x) = \beta_0 + \beta_1 x$$

- $\triangleright$  E(y|x) is the **expected value (average) of y, given a value of x**.
- $\triangleright$   $\beta_0$  is the **population intercept**.
- $\triangleright$   $\beta_1$  is the **population slope**. These are unknown constants (parameters) that we want to estimate.

The PRF represents the true, but unknown, relationship in the population.

### The Stochastic Error Term

Of course, not everyone with the same level of education has the same wage. Other factors matter (experience, innate ability, location, luck, etc.).

We capture all these other unobserved factors in a **stochastic error term**, *u*.

Our individual-level population model is:

$$y_i = \beta_0 + \beta_1 x_i + u_i$$

- $\triangleright$   $y_i$  is the wage of individual i.
- $\triangleright$   $x_i$  is the education of individual i.
- $\triangleright$   $u_i$  is the error term for individual i. It represents the deviation of individual i's actual wage from the population average,  $E(y|x_i)$ .

By definition of the conditional expectation, E(u|x) = 0. The average of the unobserved factors does not depend on the level of education.

## 2. The Sample Regression Function (SRF)

### From Population to Sample

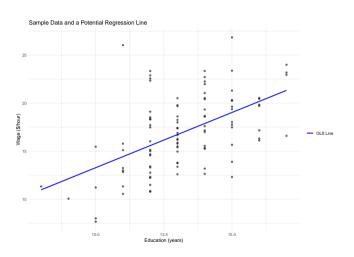

We can't observe the entire population. We only have a sample of data. Our goal is to use the sample data to *estimate* the unknown population parameters  $\beta_0$  and  $\beta_1$ .

The **Sample Regression Function (SRF)** is our estimate of the PRF:

$$\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x$$

- $\hat{y}$  (y-hat) is the **predicted** or **fitted** value of y.
- $\triangleright$   $\hat{\beta}_0$  and  $\hat{\beta}_1$  are the **estimators** of  $\beta_0$  and  $\beta_1$ . They are statistics calculated from our sample data.

# Example

### 2.1 Derivation of OLS Estimators

How do we choose the "best" values for  $\hat{\beta}_0$  and  $\hat{\beta}_1$ ? We want a line that fits the data as closely as possible.

We define the **residual**,  $e_i$ , as the difference between the actual value  $y_i$  and the fitted value  $\hat{y}_i$ :

$$e_i = y_i - \hat{y}_i = y_i - (\hat{\beta}_0 + \hat{\beta}_1 x_i)$$

The Ordinary Least Squares (OLS) method chooses  $\hat{\beta}_0$  and  $\hat{\beta}_1$  to minimize the Sum of Squared Residuals (SSR):

$$\min_{\hat{\beta}_0, \hat{\beta}_1} SSR = \sum_{i=1}^n e_i^2 = \sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i)^2$$

We square the residuals so that positive and negative errors don't cancel out, and because it penalizes larger errors more heavily.

## Derivation of OLS (Cont.)

To minimize the SSR, we use calculus: take the partial derivatives with respect to  $\hat{\beta}_0$  and  $\hat{\beta}_1$  and set them to zero. These are the **First Order Conditions (FOCs)**.

1. 
$$\frac{\partial SSR}{\partial \hat{\beta}_0} = -2 \sum_{i=1}^n (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i) = 0 \implies \sum (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i) = 0$$

2. 
$$\frac{\partial SSR}{\partial \hat{\beta}_1} = -2 \sum_{i=1}^n x_i (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i) = 0 \implies \sum x_i (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_i) = 0$$

Solving this system of two equations for the two unknowns  $(\hat{\beta}_0, \hat{\beta}_1)$  gives the OLS estimator formulas:

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2} = \frac{\mathsf{Sample Covariance}(x, y)}{\mathsf{Sample Variance}(x)}$$

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x}$$

where  $\bar{x}$  and  $\bar{y}$  are the sample means of x and y.

## 2.2 Algebraic Properties of OLS

The OLS estimators have some important algebraic properties that come directly from the FOCs:

#### 1. The sum of the OLS residuals is zero:

$$\sum_{i=1}^n e_i = 0$$

This implies that the sample average of the residuals,  $\bar{e}$ , is also zero.

# 2.2 Algebraic Properties of OLS (Cont.)

2. The sample covariance between the regressor (x) and the OLS residuals (e) is zero:

$$\sum_{i=1}^n x_i e_i = 0$$

This means the part of y that we can't explain with x (the residual) is uncorrelated with x in our sample.

3. The point  $(\bar{x}, \bar{y})$  is always on the OLS regression line. From the formula  $\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x}$ , we can write  $\bar{y} = \hat{\beta}_0 + \hat{\beta}_1 \bar{x}$ .

## 2.3 Interpreting OLS Coefficients

Let's run our wage-education regression: wage  $=\hat{eta}_0+\hat{eta}_1$  educ

```
slr_model <- lm(wage ~ educ, data = dat)
# The coefficients are:
coef(slr_model)</pre>
```

## (Intercept) educ ## 1.786342 1.149829

So our estimated SRF is:  $\widehat{wage} = 1.79 + 1.15 \times educ$ 

#### Interpretation:

- ▶ Slope  $(\hat{\beta}_1 \approx 1.15)$ : "For each additional year of education, we estimate the hourly wage to increase by **\$1.15**, on average." This is the key policy parameter.
- ▶ Intercept ( $\hat{\beta}_0 \approx 1.79$ ): "For an individual with zero years of education, we predict an hourly wage of **\$1.79**."

### 2.4 Units and Functional Form

The values of the coefficients depend on the units of measurement of y and x. We've used a **level-level** model (y and x are in their natural units).

Suppose we measured wage in cents instead of dollars.

- ▶ The new dependent variable is  $wage_{cents} = 100 \times wage$ .
- ▶ The new regression would be:  $\widehat{wage}_{cents} = (100 \times \hat{\beta}_0) + (100 \times \hat{\beta}_1) \times educ$
- ▶ Both the intercept and slope would be 100 times larger. The *interpretation* is the same, just the units change ("an extra year of education increases wage by 125 cents").

## 2.4 Units and Functional Form (Cont.)

What if we measured education in months instead of years?

The interpretation of  $\hat{\beta}_1$  would become "the estimated change in wage for an additional *month* of education." The coefficient value would be  $\frac{1}{12}$  of its original value:

From our definition,  $educ_{years} = \frac{1}{12} educ_{months}$ . Let's substitute this into the original estimated equation:

$$\begin{split} \widehat{\textit{wage}} &= \hat{\beta}_0 + \hat{\beta}_1 \textit{educ}_{\textit{years}} \\ &= \hat{\beta}_0 + \hat{\beta}_1 \left( \frac{1}{12} \textit{educ}_{\textit{months}} \right) \\ &= \hat{\beta}_0 + \left( \frac{\hat{\beta}_1}{12} \right) \textit{educ}_{\textit{months}} \end{split}$$

### Why use different functional forms?

So far, we've assumed a linear relationship: a one-unit change in x leads to the same change in y, regardless of the starting value of x.

But often, relationships are not linear. We use transformations (like logarithms) to:

- Model Non-Linear Relationships: Capture effects that are proportional or diminishing.
- Change the Interpretation: Analyze percentage changes (elasticities) instead of unit changes.
- 3. **Improve Statistical Properties**: Stabilize the variance of the error term or make the distribution of a variable more symmetric.

The most common transformations involve the natural logarithm, log().

# The Log-Level Model: log(y) on x

Here, we transform the dependent variable y:  $\log(y) = \beta_0 + \beta_1 x + u$ 

**Interpretation of**  $\beta_1$ : A one-unit increase in x is associated with a  $(100 \times \beta_1)\%$  change in y.

▶ To see this, take the derivative of the equation with respect to *x*:

$$\frac{d(\log(y))}{dx} = \beta_1$$

- ▶ Recall the calculus rule/approximation: for small changes,  $\Delta \log(y) \approx \frac{\Delta y}{y}$ .
- For a one-unit change in x ( $\Delta x = 1$ ):

$$\beta_1 = \frac{\Delta \log(y)}{\Delta x} \approx \frac{\Delta y/y}{1}$$

## Example

▶ So,  $\beta_1$  is the *proportional* change in y. We multiply by 100 to get a percentage.

**Example**: If  $log(wage) = 1.5 + 0.08 \times educ$ :

An additional year of education is associated with an approximate  $0.08 \times 100 = 8\%$  increase in wage.

# The Level-Log Model: y on log(x)

Here, we transform the independent variable x:  $y = \beta_0 + \beta_1 \log(x) + u$ 

**Interpretation of**  $\beta_1$ : A 1% increase in x is associated with a  $(\beta_1/100)$  unit change in y.

▶ To see this, take the derivative of the equation with respect to log(x):

$$\frac{dy}{d(\log(x))} = \beta_1$$

- ▶ A change in  $\log(x)$  is approximately the proportional change in x:  $\Delta \log(x) \approx \frac{\Delta x}{x}$ .
  - ► So,  $\Delta y \approx \beta_1 \Delta(\log(x)) \approx \beta_1 \frac{\Delta x}{x}$ .
  - If we consider a 1% change in x, then  $\frac{\Delta x}{x} = 0.01$ .
  - ▶ The resulting change in y is:  $\Delta y \approx \beta_1 \times (0.01) = \frac{\beta_1}{100}$ .

### Example

**Example**: price = 200 + 75 \* log(sqft) for house prices.

▶ A 1% increase in square footage is associated with a 75/100 = \$0.75 increase in price.

# The Log-Log Model: log(y) on log(x)

Here, we transform both variables. This model is very common in economics because  $\beta_1$  is an **elasticity**:  $\log(y) = \beta_0 + \beta_1 \log(x) + u$ 

**Interpretation of**  $\beta_1$ : A 1% increase in x is associated with a  $\beta_1$ % change in y.

To see this, from the model, we can write:

$$\beta_1 = \frac{d(\log(y))}{d(\log(x))}$$

Using the same approximations as before:

$$\beta_1 \approx \frac{\Delta y/y}{\Delta x/x} = \frac{\% \Delta y}{\% \Delta x}$$

This is the definition of elasticity. If we set the percentage change in x to 1% (% $\Delta x = 1$ ), then the percentage change in y is just  $\beta_1$ .

### Example

**Example**: log(sales) = 4.8 - 1.2 \* log(price) for a product.

▶ A 1% increase in price is associated with a 1.2% decrease in sales. The price elasticity of demand is -1.2.

## Other Forms: Polynomials

We can also add polynomial terms (like  $x^2$ ,  $x^3$ , etc.) to capture more complex non-linear patterns, such as diminishing returns.

**Model (Quadratic):** 
$$y = \beta_0 + \beta_1 x + \beta_2 x^2 + u$$

**Interpretation**: The effect of a change in x on y now depends on the level of x.

▶ The marginal effect of x on y is the derivative with respect to x:

$$\frac{\Delta y}{\Delta x} \approx \frac{dy}{dx} = \beta_1 + 2\beta_2 x$$

▶ A one-unit change in x is associated with a change in y of approximately  $\beta_1 + 2\beta_2 x$ .

## Example

**Example**:  $\widehat{wage} = 3.50 + 0.60 \times educ - 0.02 \times educ^2$ .

- ▶ The effect of the *first* year of education  $(x = 0 \rightarrow x = 1)$  is about \$0.60.
- The effect of the *13th* year of education  $(x = 12 \rightarrow x = 13)$  is: 0.60 + 2(-0.02)(12) = 0.60 0.48 = \$0.12.
- ▶ This captures the *diminishing returns* to education on wage.

# Summary of Interpretations

| Model Name  | Equation                              | Interpretation of $\hat{eta}_1$  |
|-------------|---------------------------------------|--|
| Level-Level | $y = \beta_0 + \beta_1 x$             | A 1-unit change in $x$ leads to a $\hat{\beta}_1$ unit change in $y$ .     |
| Log-Level   | $\log(y) = \beta_0 + \beta_1 x$       | A 1-unit change in $x$ leads to a $(100 \times \hat{\beta}_1)\%$ change in |
| Level-Log   | $y = \beta_0 + \beta_1 \log(x)$       | $y$ . A $1\%$ change in $x$ leads to a $(\hat{eta}_1/100)$ unit change in  |
| Log-Log     | $\log(y) = \beta_0 + \beta_1 \log(x)$ | $y$ . A $1\%$ change in $x$ leads to a $\hat{eta}_1\%$ change in $y$ .     |

### 2.5 Goodness-of-Fit

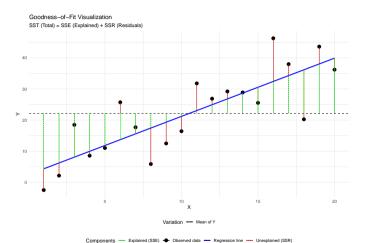

How well does our estimated line explain the variation in our dependent variable, y?

We can partition the total variation in y into two parts: the part explained by the model, and the part that is not explained.

- **SST** (Total Sum of Squares): Total variation in y.  $SST = \sum (y_i \bar{y})^2$
- SSE (Explained Sum of Squares): Variation explained by the regression.  $SSE = \sum (\hat{y}_i \bar{y})^2$
- **SSR** (Sum of Squared Residuals): Unexplained variation.  $SSR = \sum e_i^2$

It is a mathematical property that SST = SSE + SSR.

### Goodness-of-Fit Visualization

## Goodness-of-Fit: R-squared and SER

## R-squared $(R^2)$

The **R-squared** measures the proportion of the total sample variation in y that is "explained" by the regression model.

$$R^2 = \frac{SSE}{SST} = 1 - \frac{SSR}{SST}$$

- $ightharpoonup R^2$  is always between 0 and 1.
- ▶ A higher R<sup>2</sup> means the model fits the data better in-sample.
- ▶ Caution: A high  $R^2$  is not the ultimate goal of econometrics! We care more about getting an unbiased estimate of the causal effect  $\beta_1$ .

## Standard Error of the Regression (SER)

The **SER** is an estimator of the standard deviation of the population error term,  $\sigma$ . It measures the typical size of a residual (the model's "average mistake").

$$\hat{\sigma} = SER = \sqrt{\frac{SSR}{n-2}}$$

- We divide by n-2 (degrees of freedom) because we had to estimate two parameters  $(\beta_0, \beta_1)$  to get the residuals.
- ▶ SER is measured in the same units as *y*. A smaller SER is better.

## 2.6 Understanding Statistical Output

```
Let's look at the full output from R/Python/Stata for our simple regression.
summary(slr_model)
##
## Call:

```

## (Intercept) 1.7863 2.5164 0.710 0.479 ## educ 1.1498 0.1887 6.092 2.19e-08 \*\*\*

## Understanding Statistical Output (Cont.)

#### Coefficients:

- ▶ Estimate: These are  $\hat{\beta}_0$  (Intercept) and  $\hat{\beta}_1$  (educ).
- ▶ Std. Error: The standard errors of the estimates,  $se(\hat{\beta}_j)$ , which measure their sampling uncertainty.
- ▶ t value: The t-statistic used for hypothesis testing (Estimate / Std. Error).
- Pr(>|t|): The p-value for the t-test.

#### Goodness-of-Fit:

- Residual standard error: This is the SER (3.4).
- ▶ Multiple R-squared: This is our **R-squared** (0.27). The model explains about 46% of the variation in wages.

### 3. The Classical Assumptions

For our OLS estimates to have desirable statistical properties, certain assumptions must hold. These are the **Gauss-Markov Assumptions**.

- Assumption 1: Linearity in Parameters. The population model is  $y = \beta_0 + \beta_1 x + u$ .
- Assumption 2: Random Sampling. The data  $(x_i, y_i)$  are a random sample from the population described by the model.
- Assumption 3: Sample Variation in x. The values of  $x_i$  in the sample are not all the same. This is the **no perfect collinearity** assumption. If all  $x_i$  are the same, the denominator of  $\hat{\beta}_1$  is zero!
- Assumption 4: Zero Conditional Mean. E(u|x) = 0. The average value of the unobserved factors is unrelated to the value of x.
- Assumption 5: Homoskedasticity.  $Var(u|x) = \sigma^2$ . The variance of the error term is constant for all values of x.

## 3.2 The Crucial Assumption: Zero Conditional Mean

$$E(u|x)=0$$

This is the most important assumption for establishing causality.

lt means that the explanatory variable (x) must not be correlated with any of the unobserved factors (u) that affect the dependent variable (y).

**Example:** y = wage, x = educ, u = unobserved factors like innate ability, family background, motivation

Is it likely that E(u|educ) = 0? Probably not.

▶ Innate ability (u) is likely correlated with education (x). People with higher ability may find it easier to get more education.

If Cov(educ, ability) > 0, then our OLS estimate  $\hat{\beta}_1$  will be biased upwards. It will capture the effect of education and the effect of ability. This is **Omitted Variable Bias**.

### Unbiasedness of OLS

**Theorem:** Under assumptions **SLR.1** through **SLR.4**, the OLS estimators are unbiased.

$$\mathbb{E}(\hat{eta}_0) = eta_0$$
 and  $\mathbb{E}(\hat{eta}_1) = eta_1$ 

#### What does this mean?

- Unbiasedness is a property of the procedure of OLS estimation.
  - If we could draw many, many random samples from the population and calculate  $\hat{\beta}_1$  for each sample, the *average* of all these estimates would be equal to the true population parameter,  $\beta_1$ .
- Our estimate from any single sample might be higher or lower than the true value, but on average, we get it right.
  - ► This property relies critically on the Zero Conditional Mean assumption (SLR.4). If SLR.4 fails, OLS is biased.

#### Variance of OLS Estimators

We also want our estimators to be precise, meaning they don't vary too much from sample to sample. This is measured by their sampling variance.

**Theorem:** Under assumptions **SLR.1** through **SLR.5** (all five Gauss-Markov assumptions), the variance of the OLS slope estimator is:

$$Var(\hat{eta}_1) = rac{\sigma^2}{\sum_{i=1}^n (x_i - \bar{x})^2} = rac{\sigma^2}{SST_x}$$

Consult the appendix for a derivation.

#### Determinants of the Variance

What determines the precision of our estimate?

- 1. The error variance,  $\sigma^2$ : More "noise" in the relationship (larger  $\sigma^2$ ) leads to a larger variance for  $\hat{\beta}_1$ .
- 2. The total sample variation in x,  $SST_x$ : More variation in our explanatory variable (x) leads to a *smaller* variance for  $\hat{\beta}_1$ . We learn more about the slope when our x values are more spread out.
- 3. The sample size, n: A larger sample size generally increases  $SST_x$ , which decreases the variance of  $\hat{\beta}_1$ .

### 4. Introduction to Multiple Linear Regression

Simple Linear Regression is often inadequate because we can't control for other factors that might be important. This leads to omitted variable bias.

The solution is to include those other factors in the model. This is **Multiple Linear Regression (MLR)**:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_k x_k + u$$

Now we have k explanatory variables.

- $\triangleright$   $\beta_j$  is the effect of a one-unit change in  $x_j$  on y, holding all other explanatory variables  $(x_1,...,x_{j-1},x_{j+1},...x_k)$  constant.
- ► This is the concept of *ceteris paribus* (all else equal). MLR allows us to isolate the effect of one variable while mathematically controlling for the others.

#### 4.1 OLS Estimation in MLR

The principle is the same: we choose  $\hat{\beta}_0, \hat{\beta}_1, ..., \hat{\beta}_k$  to minimize the Sum of Squared Residuals (SSR).

The formulas are complex (usually done with matrix algebra) but are easily handled by software:

- ightharpoonup lm(y ~ x1 + x2, data=df) in R
- ▶ reg y x1 x2 in Stata
- Python:

from sklearn.linear\_model import LinearRegression
LinearRegression().fit(X, y)

### Variance of OLS Estimators in MLR

The variance of a coefficient  $\hat{\beta}_j$  now depends on **multicollinearity** – how correlated  $x_j$  is with the *other* explanatory variables.

$$Var(\hat{eta}_j) = rac{\sigma^2}{SST_j(1-R_j^2)}$$

- ▶  $SST_j$  is the total variation in  $x_j$ .
- $ightharpoonup R_j^2$  is the R-squared from a regression of  $x_j$  on all other explanatory variables in the model.
- ▶ If  $x_j$  is highly correlated with other x's,  $R_j^2$  will be close to 1, making the denominator small and  $Var(\hat{\beta}_j)$  very large. This is **imperfect multicollinearity**.
- ▶ The **no perfect collinearity** assumption for MLR means that no  $x_j$  can be a perfect linear combination of the others (i.e.,  $R_i^2 \neq 1$ ).

### Heuristic Derivation of the t-statistic

To test a hypothesis about a single coefficient (e.g.,  $H_0: \beta_j = 0$ ), we want to see how many standard deviations our estimate  $\hat{\beta}_j$  is from the hypothesized value.

A standardized statistic would look like this:

Statistic = 
$$\frac{\text{Estimate} - \text{Hypothesized Value}}{\text{Standard Deviation of Estimate}} = \frac{\hat{\beta}_j - 0}{sd(\hat{\beta}_j)}$$

If we knew the population standard deviation  $sd(\hat{\beta}_j) = \sqrt{\frac{\sigma^2}{SST_j(1-R_j^2)}}$ , this statistic would follow a standard normal (Z) distribution.

The Problem: We don't know the population error variance,  $\sigma^2$ .

The Solution: We replace  $\sigma^2$  with its sample estimate,  $\hat{\sigma}^2 = \frac{SSR}{n-k-1}$ . This gives us the standard error of the estimate,  $se(\hat{\beta}_j)$ .  $se(\hat{\beta}_j) = \sqrt{\frac{\hat{\sigma}^2}{SST_j(1-R_j^2)}} = \frac{\hat{\sigma}}{\sqrt{SST_j(1-R_j^2)}}$ 

# Why a t-statistic? (From Z to t)

Because we had to estimate  $\sigma^2$ , we introduce extra sampling variability into our statistic.

The ratio of our estimate to its standard error is no longer normally distributed. It follows a **t-distribution**.

$$t = rac{\hat{eta}_j - eta_j}{se(\hat{eta}_i)} \sim t_{n-k-1}$$

- ▶ The **t-distribution** looks very similar to the normal distribution but has "fatter tails," reflecting the added uncertainty from estimating  $\sigma^2$ .
- ▶ It is characterized by its **degrees of freedom (df)**, which for MLR is df = n k 1.
  - ightharpoonup n =sample size, k + 1 =number of estimated parameters (including the intercept)
- As the sample size (n) gets large, the t-distribution converges to the standard normal distribution.

### Hypothesis Testing in Regression

Once we've estimated our model,  $\hat{y} = \hat{\beta}_0 + \hat{\beta}_1 x_1 + \cdots + \hat{\beta}_k x_k$ , we need to ask: **Is the relationship we found statistically significant?** 

- ightharpoonup Our estimates  $\hat{\beta}_0$  and  $\hat{\beta}_j$  are based on a *sample* of data. They are subject to sampling variability.
- It's possible that the true relationship in the *population* is zero ( $\beta_1 = 0$ ), and we just found a non-zero  $\hat{\beta}_1$  by random chance.

Hypothesis testing allows us to use our sample evidence to make a probabilistic statement about the true, unknown population parameters.

We will focus on two key tests: 1. **The t-test**: For testing the significance of a *single* coefficient. 2. **The F-test**: For testing the *joint* significance of multiple coefficients or the model as a whole.

## 3.1 The t-Test: Significance of a Single Coefficient

The t-test is our tool for testing a hypothesis about a single coefficient. The most common hypothesis is that a variable has no effect on the dependent variable.

### Hypotheses for a single coefficient $\beta_j$ :

**Null Hypothesis**  $(H_0)$ : The variable has no effect.

$$H_0: \beta_i = 0$$

Alternative Hypothesis (H<sub>A</sub>): The variable does have an effect.

$$H_A: \beta_j \neq 0$$

#### t-statistic

**The t-statistic**: We calculate a t-statistic, which measures how many standard errors our estimated coefficient is away from the hypothesized value (zero).

$$t = rac{\mathsf{Estimate} - \mathsf{Hypothesized} \; \mathsf{Value}}{\mathsf{Standard} \; \mathsf{Error}} = rac{\hat{eta}_j - \mathsf{0}}{\mathsf{se}(\hat{eta}_j)}$$

#### **Decision Rule:**

- **p-value**: Most software reports a p-value. If the p-value is less than our chosen significance level (e.g.,  $\alpha = 0.05$ ), we **reject the null hypothesis**. This means we have statistically significant evidence that  $x_i$  affects y.
- ▶ Rule of Thumb: For large samples, a t-statistic with an absolute value greater than 2 (or more precisely, 1.96) is typically significant at the 5% level.

### 3.1 The F-Test: Testing Joint Significance

The F-test is used to test hypotheses about **multiple** coefficients at the same time. Its most common use is to test the **overall significance** of the regression model.

**Overall Significance F-Test**: This tests whether *any* of our independent variables have an effect on the dependent variable.

- ► **Model**:  $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k + u$
- ▶ **Null Hypothesis** ( $H_0$ ): *None* of the independent variables have an effect on y. The model has no explanatory power.

$$H_0: \beta_1 = \beta_2 = \cdots = \beta_k = 0$$

▶ Alternative Hypothesis ( $H_A$ ): At least one of the coefficients is not zero. The model has some explanatory power.

$$H_A$$
: At least one  $\beta_i \neq 0$  for  $j = 1, \dots, k$ 

#### F statistic

**The F-statistic**: The F-statistic is calculated by comparing the fit of our full model (the 'unrestricted' model) to the fit of a model with no independent variables (the 'restricted' model, where we force the null hypothesis to be true).

- ▶ A large F-statistic suggests that our variables jointly explain a significant amount of the variation in *y*.
- Like the t-test, we typically look at the **p-value** for the F-statistic. If p < 0.05, we reject the null and conclude our model is jointly significant.

### 3.1 t-test vs. F-test: A Summary

It's crucial to understand when to use each test. A group of variables can be jointly significant (F-test) even if no single variable is individually significant (t-tests).

| Feature         | t-test  | F-test   |
|-----------------|---|--|
| Scope           | One coefficient at a time   | Two or more coefficients at a time   |
| Typical Use     | Is <i>this specific variable</i> significant?                               | Is this <i>group of variables</i> jointly significant? OR Is the <i>model as</i> a whole useful? |
| Null Hypothesis | $H_0: eta_j = 0$  | $H_0: \beta_1=\beta_2=\cdots=0$  |
| Test Statistic  | $t = rac{\hat{eta}_j}{se(\hat{eta}_j)}$                                    | Compares Restricted vs. Unrestricted sum of squares  |
| Key Question    | "Does education significantly affect wage, holding other factors constant?" | "Does a person's work experience, measured by exper and exper^2, jointly affect their wage?"     |

# MLR Example: Wage, Education, and Experience

Let's add exper (years of work experience) to our model.

## -7.3544 -1.9212 0.1218 2.1522 7.5290

##

```
mlr_model <- lm(wage ~ educ + exper, data=dat_mlr)</pre>
summary(mlr model)
##
## Call:
## lm(formula = wage ~ educ + exper, data = dat_mlr)
##
## Residuals:
##
      Min 10 Median 30
                                       Max
```

## Coefficients:
## Estimate Std. Error t value Pr(>|t|)
## (Intercept) 2.82941 2.64978 1.068 0.2883

### Interpretation with Controls

#### Interpretation:

- educ:  $\hat{\beta}_1 \approx 1.12$ : Holding experience constant, one more year of education is associated with a \$1.12/hr increase in wages, on average.
- ightharpoonup exper:  $\hat{eta}_2 \approx 0.19$ : Holding education constant, one more year of experience is associated with a \$0.19/hr increase in wages, on average.
- ▶ The R-squared increased, suggesting this model explains more variation in wages.
- ► The t-statistics tell us whether these coefficients are statistically distinguishable from zero.

# Appendix: Derivation of Variance of OLS Slope Estimator

Consider the univariate linear regression model:

$$y_i = \alpha + \beta x_i + \epsilon_i$$
 where  $\epsilon_i \sim \text{iid } N(0, \sigma^2)$ 

The OLS estimator for the slope coefficient  $\beta$  is:

$$\hat{\beta} = \frac{\sum_{i=1}^{n} (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^{n} (x_i - \bar{x})^2} = \frac{S_{xy}}{S_{xx}}$$

where 
$$S_{xx} = \sum (x_i - \bar{x})^2$$
 and  $S_{xy} = \sum (x_i - \bar{x})(y_i - \bar{y})$ .

## Rewriting the Estimator

Substitute  $y_i = \alpha + \beta x_i + \epsilon_i$  into the estimator:

$$\hat{\beta} = \frac{\sum (x_i - \bar{x})(\alpha + \beta x_i + \epsilon_i - \bar{y})}{S_{xx}}$$

$$= \beta + \frac{\sum (x_i - \bar{x})\epsilon_i}{S_{xx}}$$

Since 
$$Var(\hat{\beta}) = Var\left(\beta + \frac{\sum (x_i - \bar{x})\epsilon_i}{S_{xx}}\right) = Var\left(\frac{\sum (x_i - \bar{x})\epsilon_i}{S_{xx}}\right)$$

### Variance Derivation

Given that  $\epsilon_i$  are iid with  $Var(\epsilon_i) = \sigma^2$ :

$$\begin{aligned} \operatorname{Var}(\hat{\beta}) &= \frac{1}{S_{xx}^2} \operatorname{Var}\left(\sum (x_i - \bar{x})\epsilon_i\right) \\ &= \frac{1}{S_{xx}^2} \sum (x_i - \bar{x})^2 \operatorname{Var}(\epsilon_i) \quad \text{(by indep., variance of sum} = \operatorname{sum of variances}) \\ &= \frac{\sigma^2}{S_{xx}^2} \sum (x_i - \bar{x})^2 \quad \text{(Var} = \sigma^2, \text{ take constant out of sum)} \\ &= \frac{\sigma^2}{S_{xx}} \end{aligned}$$

The variance of the OLS slope estimator is  $Var(\hat{\beta}) = \frac{\sigma^2}{\sum_{i=1}^n (x_i - \bar{x})^2}$ 

# Linearity and Normality of $\hat{\beta}$

Since  $\hat{\beta}$  is a linear combination of the  $\epsilon_i$  (which are normally distributed),  $\hat{\beta}$  is also normally distributed:

$$\hat{eta} \sim N\left(eta, \mathsf{Var}(\hat{eta})\right)$$

From the previous derivation, we know:

$$\mathsf{Var}(\hat{\beta}) = \frac{\sigma^2}{S_{\mathsf{xx}}}$$

Thus, the **sampling distribution of**  $\hat{\beta}$  is:

$$\hat{\beta} \sim N\left(\beta, \frac{\sigma^2}{\sum (x_i - \bar{x})^2}\right)$$

### Standardized Distribution

If we standardize  $\hat{\beta}$ , we obtain a standard normal distribution:

$$rac{\hat{eta} - eta}{\sqrt{\mathsf{Var}(\hat{eta})}} = rac{\hat{eta} - eta}{\sigma/\sqrt{\mathsf{S}_\mathsf{xx}}} \sim \mathit{N}(0,1)$$

#### **Key Implications:**

- 1. **Unbiasedness**: The expected value of  $\hat{\beta}$  is the true parameter  $\beta$ .
- 2. **Normality**: The distribution is exactly normal when errors are normal.
- 3. Variance decreases with:
  - ▶ Larger sample size n (generally increases  $S_{xx}$ ).
  - ▶ Greater spread in  $x_i$  (increases  $S_{xx}$ ).
  - ▶ Smaller error variance  $\sigma^2$ .
